5 DENSITY-DEPENDENT SELECTION

6
7 Density-dependent selection is a special type of natural
8 selection in which survival and reproduction depend on
9 the population density of other individuals of the same
10 species. Density in this context can be thought of as the
11 number of other individuals nearby. The action of den-
12 sity-dependent selection may be influenced by the vary-
13 ing density of neighbors during different life stages. For
14 instance, insect survival from egg to adult may depend
15 on the density of larvae, whereas the number of eggs
16 laid by females may vary with adult density.

17 **Development of Logistic Theory.** Robert MacAr-
18 thur (1962) was the first to develop the mathematical
19 relationship between ecological theories of population
20 growth and the effect of natural selection at different
21 densities. MacArthur accomplished this with the aid of
22 the logistic equation of population growth. This ecolog-
23 ical model states that populations at low densities will
24 grow exponentially at the intrinsic rate of population
25 growth (r). The logistic model also assumes that, as a
26 population becomes more crowded, the rate of growth
27 declines. The population ceases to grow when it reaches
28 its carrying capacity (K), which is the equilibrium popu-
29 lation size.

30 Classical theories of natural selection measured fit-
31 ness by calculating the intrinsic rate of growth (r) of a
32 population. This parameter tends to be maximized by
33 maximizing fertility and survival at low population den-
34 sity. MacArthur extended this idea by suggesting that, at
35 high population density, the population size at carrying
36 capacity (K) would be an appropriate measure of fitness.
37 This theory has sometimes been referred to as r and K
38 selection, drawing from the two parameters of the lo-
39 gistic equation. In 1971, Roughgarden generalized these
40 ideas by suggesting that fitness may be equated with per
41 capita rates of reproduction and population growth. An
42 example of this theory is shown in *Figure 1*. At low popu-
43 lation density, natural selection will favor the increase
44 and ultimate fixation of the AA allele because the AA
45 homozygotes have highest fitness. However, at high den-
46 sity, natural selection would favor increases in the alter-
47 native AA allele. Most importantly, the outcome of evo-
48 lution depends on the density of the environment.

49 **Trade-offs at Low and High Densities.** A key to
50 this theory is the idea of trade-offs. As illustrated in Fig-
51 ure 1, the genotype that is best at low density has the
52 lowest fitness at high density and vice versa. If these
53 types of trade-offs did not exist, then there would be one
54 best genotype for all environments. Although there are

"Insert period" PE

"1's should be subscripts" PE

"2 should be subscript" PE

55 no first principles that can be invoked to prove that
56 trade-offs exist, there are some simple arguments that
57 suggest this is a reasonable assumption. Martin Cody
58 (1966), first developed this idea in the context of life
59 history evolution. Cody argued that all organisms must
60 contend with limited amounts of time and energy. As
61 soon as they devote more of their time and energy to,
62 say, reproduction, they will have less time and energy
63 for other activities, such as competing for food.

64 If the trade-off assumption is valid, those populations
65 that have evolved to grow fastest at low density should
66 do poorly at high density and vice versa. These ideas
67 have been tested by maintaining populations of fruit flies
68 (*Drosophila melanogaster*) at very low and very high
69 densities. After eight generations of evolution, the popu-
70 lation growth rates of the high- and low-density adapted
71 populations differentiated, and the predicted trade-offs
72 were observed (Figure 2).

73 These populations of fruit flies have been studied in
74 more detail to determine which traits changed to cause
75 the observed differences in population growth rates. At
76 least three larval behavioral traits become differentiated
77 between the low- and high-density populations. The
78 high-density populations show elevated larval feeding
79 rates compared to the low-density populations. In fruit
80 flies, it is known that high feeding rates translate into
81 increased competitive ability for limited food, which is
82 certainly at a premium in crowded environments. How-
83 ever, larvae with high feeding rates show reduced sur-
84 vival at low density. Feeding rates then explain, at least
85 in part, the trade-offs observed in Figure 2. When pop-
86 ulations of fruit flies adapted to high larval densities are
87 moved back to low densities, the flies' feeding rates rap-
88 idly evolve to a lower level, presumably as a conse-
89 quence of the reduced survival of fast feeders at low
90 density. Individuals from populations adapted to high
91 density also move greater distances while foraging com-
92 pared to individuals from populations adapted to low
93 density. Finally, larvae from populations that have
94 evolved at high densities are less likely to metamor-
95 phose into adults (pupate) on the surface of the food
96 and tend to crawl farther from the food surface in search
97 of a pupation site. This altered behavior also improves
98 survival because larvae that pupate on the surface of the
99 food in crowded cultures showed greatly elevated mor-
100 tality rates.

101 **Development of Verbal Theory.** At the same time
102 as MacArthur and Roughgarden were developing their
103 quantitative theories of density-dependent natural selec-
104 tion, an extensive verbal theory of r and K selection was
105 developed. A verbal theory is simply one in which the
106 major assumptions and conclusions are argued in words
107 without reliance on formal mathematics. Verbal theories
108 are acceptable ways of developing ideas in biology.
109 However, the logic supporting the conclusions of verbal
110 theories is not always as obvious as it is with mathe-
111 matical theories. The verbal theories of r and K selection
112 suggested populations that evolved at high density,

113 called *K*-selected, should be composed of individuals
114 with increased competitive ability, larger body size, de-
115 layed reproduction, and repeated reproduction over
116 many years, or iteroparity. Populations evolved at low
117 density, or *r*-selected, under this theory would display
118 the opposite set of characteristics: reduced competitive
119 ability, small body size, high levels of reproduction early
120 in life, and survival over fewer reproductive years.

121 Many of the logical flaws with the verbal theory of *r*
122 and *K* selection quickly became obvious to many sci-
123 entists. For instance, the mathematical theories devel-
124 oped by Roughgarden and MacArthur do not have adults
125 of different ages; instead, all reproduction takes place
126 at a single instant in time. The verbal theories mistak-
127 enly inferred that the evolution of high carrying capac-
128 ities would lead to adults surviving and reproducing over
129 many years. The demise of the verbal theory was sig-
130 naled by a series of review papers by Steven Stearns in
131 1976 and 1977 that clearly revealed many of the flaws in
132 the verbal theory.

133 **Studies of Wild Populations.** How important is
134 density-dependent natural selection in wild popula-
135 tions? This has been a difficult question to answer for
136 several reasons. Much of the early empirical work fo-
137 cused on natural populations that were thought to have
138 experienced different density environments. Any differ-
139 ence among these populations in characteristics like fer-
140 tility and competitive ability was then attributed to den-
141 sity-dependent natural selection. The problem with
142 these types of studies is that historical information on
143 the past density conditions of populations was often an-
144 ecdotal or incomplete. Likewise, because these natural
145 populations were not under human control, it was often
146 impossible to rule out other factors, such as predation
147 and herbivory, that may have systematically differed be-
148 tween populations. Despite these problems, there are
149 some well-studied natural populations where density-
150 dependent selection is important.

151 Soay sheep in Scotland, for example, show pheno-
152 typic differences in coat color and horn type. Both of
153 these characteristics are under single- or two-locus ge-
154 netic control. Paul Moorcroft and his colleagues (1996)
155 showed that females with dark coats and small twisted
156 horns survived better at low densities than females with
157 light coats and untwisted horns. However, at high popu-
158 lation densities the advantage was reversed. Because
159 population densities vary dramatically in the studied
160 populations, density-dependent selection is probably im-
161 portant for the maintenance of the genetic polymor-
162 phisms in horn shape and coat color.

163 Populations that grow according to the logistic model
164 are expected ultimately to reach an equilibrium size
165 equal to the carrying capacity. However, depending on
166 the characteristics of the population, the approach to
167 this equilibrium can be gradual and smooth, or it may
168 be oscillatory, with the population overshooting and un-
169 dershooting the carrying capacity by decreasing
170 amounts each generation, or some populations may

171 never settle down to the equilibrium predicted by the
172 logistic equation. These different scenarios reflect dif-
173 ferent kinds of population stability. Just as density-de-
174 pendent natural selection may affect population growth
175 rates, it may also affect the stability of population size.
176 Population stability is an important area of biological
177 research because the long-term persistence of popula-
178 tions, especially endangered species, can be affected by
179 their tendency to fluctuate or stabilize. Theoretical work
180 has come up with conflicting predictions. In some cases,
181 density-dependent selection can lead to increased sta-
182 bility of a population, whereas in other cases, stability
183 decreased. There has been one large experiment per-
184 formed with fruit flies. In this study, fruit flies were
185 placed in an environment that caused the population
186 size to fluctuate. Despite evidence of substantial genetic
187 change in these populations as they adapted to the suc-
188 cessive environments, none of these changes appear to
189 have affected the stability of the populations. In this
190 case, the evolution of density-dependent traits did not
191 affect the stability of population size.
